Image Rectification Lab Answers

Question 1: Describe the difference between the two image rectification techniques you used and the associated errors that might be introduced when using each of these techniques.

> **Image-to-map rectification** - uses real-world coordinates & GCPs to transform images to standard map projections; errors include coordinate measurement mistakes & projection distortions • **Image-to-image registration** - aligns one image to another without map coordinates; errors from feature matching problems & scale differences • **Usage** - use image-to-map for precise geographic positioning, use image-to-image for quick comparisons when map coordinates aren't needed

Question 2: Is the spatial distribution of your GCPs important to ensure acceptable rectification? Why or why not?

> **Yes, super important** - evenly distributed GCPs across entire image area ensure uniform geometric correction throughout • **Clustered GCPs suck** - putting all GCPs in one area leads to poor rectification & higher RMS errors in uncovered regions •

Bad distribution = bad results - causes geometric distortions & unreliable rectification outside the GCP coverage area

Question 3: What is your definition of the ideal Ground Control Point (GCP)?

Clear & identifiable - must be easily seen in both source image & reference map, like road intersections or building corners • **Permanent & stable** - features that don't change over time, have high contrast with surroundings for precise location • **Small & accurate** - point-like features rather than large areas to minimize location uncertainty & provide accurate coordinates
